Evaluating Psychological Interventions: Efficacy, Effectiveness, Client Progress, and Cost

Robert J. Flynn
University of Ottawa

Before commenting on Hiebert’s (1997 [this issue]) paper, I think it is useful to summarize his argument, as accurately and succinctly as possible, in the following propositional form (1) Fiscal restraint has resulted in an increased emphasis within counselling, on accountability, results, and evaluation. (2) To cope successfully with the challenge of accountability, counsellors will have to make evaluation an integral part of the counselling process. (3) Doing so will require an expanded definition of acceptable evidence that includes informal evidence, and encourages counsellors to use informal measures to document client change, such as checklists, the “life line” technique, portfolios, observation forms, cognitive mapping, self-monitored data, authentic assessment, and performance assessment. (4) This new approach to evaluating counselling will need to be collaborative and proactive, involving agreement among all stakeholders—funders, special interest groups, managers, counsellors, and clients—on the nature of the service provided, the approach to evaluation, and the evidence that will indicate success and permit stakeholders to recognize the effectiveness and value of the service rendered. (5) To guide evaluation practice, agencies will need a workable and integrated counselling-evaluation model that includes a policy statement that identifies stakeholders (including funders, special interest groups, clients, significant others, counsellors, supervisors, managers, and coordinators); defines evaluation roles, responsibilities, time frames, and acceptable evidence of success; delineates intervention factors; describes agency factors; and defines communication factors. (6) Finally, counselling needs to emphasize both process, the traditional focus of counselling training and practice, and outcome, a hitherto neglected aspect that needs to be evaluated through built-in procedures.

Critique of Hiebert’s Argument

In the present context, I prefer the term psychological interventions to that of counselling. The former is more general and, as used here, considers counselling and psychotherapy as virtually identical processes that pose the same evaluative questions.

Several of Hiebert’s assertions strike me as correct, and I wish to acknowledge the overall utility of his important contribution. I am in essential agreement with propositions 1, 2, and 6 (as formulated above).
Furthermore, if researchers were added to Hiebert's lists of stakeholders in propositions 4 and 5, I would also readily agree with them as well. I disagree, however, with Hiebert's third proposition, which is central to his argument. I shall thus concentrate on it here. In doing so, I shall propose what I believe is a more comprehensive evaluation model and a better and more feasible alternative for assessing client progress.

Hiebert's third proposition seems problematic to me, for at least three reasons. First, I think it exaggerated the importance of informal evaluation methods and measures, compared with formal ones. Second, the suggested need to include evaluation as an integral part of counselling (with which I strongly agree) in no way requires, in my opinion, a primary reliance on informal procedures and measures to document client change. On the contrary, formal (i.e., standardized and psychometrically sound) and feasible methods and instruments already exist that practitioners are beginning to use to evaluate the status of their clients before, during, and after psychological interventions. Informal methods and instruments may sometimes be useful adjuncts to such formal procedures but, in my opinion, they cannot be credible substitutes for them. (For the sake of clarity, let me also state my view that any method or instrument that possesses adequate standardization, norms, reliability, and validity should be considered to be formal rather than informal. Such tools may also be feasible for routine use in clinical decision-making, but they are not automatically so.)

My third criticism of Hiebert's proposition 3 is that his underlying evaluation model seems incomplete. While agreeing with him that the monitoring of individual client progress is crucial, this aspect is but one of the four that I see as essential in a comprehensive approach to evaluation. As the title of my paper suggests, a comprehensive model has to assess not only client progress but also the efficacy, effectiveness, and cost of psychological interventions.

Finally, concerning Hiebert's argument as a whole, I believe that he does not place enough emphasis on the links that need to exist between researchers and practitioners. It is surprising, for example, that his listing of stakeholders (in propositions 4 and 5) does not include researchers. Convincing assessments of the worth of psychological interventions, however, will require long-term strategic partnerships between practitioners and researchers (Goldfried & Wolfe, 1996). Using mainly formal, well standardized methods, members of these two groups will need to collaborate in the gathering of reliable and valid data on the efficacy, effectiveness, client progress, and costs associated with a wide range of psychological interventions. Examples of such collaboration are beginning to appear, in places such as Ontario and Pennsylvania (Goldfried & Wolfe, 1996).
A Comprehensive Four-Dimensional Approach to Evaluating Psychological Interventions

A recent special issue of the *American Psychologist* (October, 1996) was devoted to the outcome assessment of psychotherapy. Most of the articles in it are directly relevant to the questions raised in Hiebert’s paper (which, it should be noted, he had already submitted to the *Canadian Journal of Counselling* before the special *American Psychologist* issue appeared). In preparing my paper, I have relied heavily on the research and reflections contained in this “state of the art” issue of the *American Psychologist*, which synthesizes many of the advances in the outcome evaluation of psychological interventions appearing in the recent literature.

There are four basic questions that may be asked about any psychological intervention and that need to be distinguished carefully from one another (see Howard, Mora, Brill, Martinovich, & Lutz, 1996, Newman & Tejeda, 1996): (1) an *efficacy* question—does the intervention work under the special experimental, controlled conditions of the psychological laboratory? (2) an *effectiveness* question—does it work in practice, under real-world conditions? (3) a *client progress* question—is it working for this particular client? And (4) a *cost* question—how expensive is it? Hiebert’s model focuses almost exclusively on the third (client-progress) question without adequate attention to the other three.

*Clinical scientists* focus on the first (efficacy) question, asking whether a new intervention produces better results than some commonly used intervention or control condition (Howard et al., 1996). The usual method is the randomized clinical trial (RCT), which is designed to have optimal internal validity so that any mean differences among treatment conditions may be attributed to the treatment conditions rather than to some extraneous cause. RCTs use random assignment of clients to treatment conditions, clear specification of the treatments in the form of detailed treatment manuals, selection of clients according to strict inclusion and exclusion criteria, and monitoring of the integrity with which the interventions are actually delivered. RCTs maximize internal validity but often at the expense of external validity, i.e., the degree to which findings may be generalized to other clients, practitioners, or settings (Howard et al., 1996; Seligman, 1996a).

*Mental health service researchers* concentrate on the second (effectiveness) and fourth (cost) questions, asking whether the new intervention produces good outcomes in the real-world settings of clinics, service agencies, and private-practice offices (Howard et al., 1996), and at what cost (Knapp, 1995; Yates, 1996). Although service researchers may use RCTs, their preferred method is often the naturalistic quasi-experiment in which assignment to comparison groups (e.g., clients with good vs.
Evaluating Psychological Interventions

poor outcomes) is not random. A good example is the recent Consumer Reports retrospective survey (Consumer Reports, 1995; Seligman, 1995, 1996a, 1996b), which concluded that psychotherapy worked very well in the real world. Effectiveness studies often have strong external validity (i.e., generalizability to other clinicians, settings, and clients) but weak internal validity (i.e., observed outcomes may be due to pre-treatment differences on variables other than the independent variable of interest). Replication of the results from such effectiveness studies is thus essential.

Practising clinicians are most interested in the third (client-progress) question of how well an intervention is working for a particular client. The focus is on what is happening to the individual client during (and not only after) the intervention. This, as Hiebert rightly insists, is the most important concern of the practitioner. Fortunately, recent client-oriented research has made possible the systematic assessment of client progress by means of formal, well standardized, reliable, and valid methods.

Monitoring Client Progress through Individual Client Profiling

I do not share Hiebert's belief that practitioners will be able to generate credible evidence of client progress and the worth of counselling through the use of mainly informal evaluation methods. In my opinion, a better and more feasible alternative is to be found in the client-profiling method developed by Howard and his colleagues (Howard et al., 1996). This technique grew out of a dosage model of psychotherapeutic effectiveness, according to which a lawful relationship exists between the log of the number of intervention sessions and the normalized probability of client improvement (Howard, Kopta, Krause, & Orlinsky, 1986). This log-normal model, according to which more and more sessions are needed to produce additional client gains, suggested that psychotherapeutic improvement occurs in three sequential and causally related phases (Howard, Lueger, Maling, & Martinovich, 1993). These are remoralization of the client's sense of well-being (typically a rapid phase that takes only a few sessions), remediation of symptoms (a longer phase that refocuses the client's coping skills on the obtaining of symptomatic relief), and rehabilitation of life functioning (the most gradual phase and one that helps the client learn new ways of handling problem-causing relationship patterns, work habits, or personal attitudes; Howard et al., 1996).

According to this three-phase model, different interventions and outcomes are appropriate during different phases of counselling, with the outcome criteria for the successive phases being subjective well-being, symptoms, and life functioning, respectively. Standardized scales for measuring each outcome have been developed (for descriptions, see Howard, Brill, Lueger, O'Mahoney, & Grissom, 1995; Howard, Orlinsky,
& Lueger, 1995; and Sperry, Brill, Howard, & Grissom, 1996). An instru­
ment called the Mental Health Index (MHI) serves as an overall measure
of outcome and consists of the sum of the subjective well-being score, the
current symptom total score, and the current life functioning total score.
The MHI has good internal consistency (.87) and test-retest reliability
(.82), discriminates well between distressed and non-distressed individ­
uals, and has norms based on over 6,500 clients (Howard et al., 1996).

Plotting the course of an intervention with a particular client on the
MHI is straightforward, with periodic assessments being made before,
during, and after the intervention. The system includes an individualized
criterion of success against which each client’s progress can be assessed,
namely, the individual client’s expected progress, given his or her initial
clinical characteristics (e.g., the severity and chronicity of the presenting
problem, and the client’s confidence that the intervention will help).
The client-profiling system allows an expected MHI score to be generated
for each intervention session, which can then be compared graphically
with the client’s observed MHI session scores.

As this new type of client-focused evaluative research increases and
is linked with growing knowledge derived from research on the other
three dimensions (efficacy, effectiveness, and cost), we may expect addi­
tional standardized client-monitoring systems to emerge (see Newman &
Tejeda, 1996). The routine use of client profiling in clinical settings
would bring several benefits. First, a practitioner could compare a client’s
actual progress with his or her expected progress to evaluate the appro­
priateness of the intervention, to plan further intervention, or to request
a clinical consultation when the client was not progressing as rapidly as
expected (Howard et al., 1996). Second, service agencies would have a
feasible means of allocating clients to more or less experienced clinici­
ans, based on the different expected rates of progress of clients who
differ in their presenting characteristics. Third, different interventions,
clients, practitioners, and agencies could be compared, based on clients’
progress during interventions and on their final outcomes. Fourth, col­
laboration between practitioners and researchers would be encouraged:
the former would have a better appreciation of the practical utility of
research, and the latter would have a keener understanding of the need
to focus on client-progress issues and to relate them to research on the
other key dimensions of efficacy, effectiveness, and cost.

In conclusion, use of the formal method of client profiling, with its
emphasis on monitoring client status before, during, and after interven­
tion, together with improved data from efficacy, effectiveness, and cost
studies, could finally begin to provide the convincing evidence of the
worth of counselling that Hiebert and others desire (e.g., Lambert &
Cattini-Thompson, 1996). The use of such procedures would also be
responsive to the recurring calls for standardized outcome assessment
that are encountered in the counselling literature (Sexton, 1996, provides but the latest example) and would avoid the serious problems related to reliability, validity, and, ultimately, credibility that I believe are inherent in informal methods and measures. The latter should play at best a secondary, adjunctive role in the evaluation of psychological interventions.
